Electroproduction of Nucleon Resonances in a Relativistic Quark Model*

F. Ravndal
California Institute of Technology, Pasadena, California 91109
(Received 22 March 1971)

A relativistic version of the symmetric quark model is used to calculate the inelastic electron-proton scattering amplitudes in the resonance region. Including all the nucleon states of the harmonic-oscillator baryon spectrum, we find good agreement with the three prominent peaks in the cross section. The part of the cross section coming from longitudinally polarized virtual photons is small, as recently observed in the resonance region.

I. INTRODUCTION

One of the most promising fields of experimental high-energy physics during the last few years has turned out to be the inelastic scattering of electrons off protons and neutrons.1 By observing only the final electron, one has the possibility of obtaining detailed information about the internal structure of the nucleons. One may hope this will have the same important consequences as the similar experiments of Franck and Hertz had for the understanding of atomic structure.

If one plots the measured cross section at a fixed scattering angle as a function of the energy $E'$ of the final electron as in Fig. 1, the salient features of the data are the following:

(a) At low energy transfer to the nucleon, a few prominent bumps in the cross section, dying rapidly away with increasing incident electron energy (increasing momentum transfer);

(b) At large energy transfers, the domination of a continuous background which varies slowly with increasing momentum transfer.

At zero momentum transfer the inelastic electron scattering gives the total absorption cross section for real photons. In this case we know that the bumps are due to nucleon resonances. The continuous part will then correspond to what is called "Pomeranchuk exchange" in Regge language.

At the present time we have almost no real theoretical understanding of this latter part of the cross section. On the other hand, since the introduction of the quark model,2 considerable insight has been gained into the classification and interactions of baryons and their resonances.

In this paper we will investigate electroproduction of nucleon resonances in the framework of the symmetric quark model picturing the baryon as a system of three quarks bound together by harmonic forces. This reaction being a highly relativistic process, there is little reason to believe that a nonrelativistic formulation of the quark model should be successful. As shown by Thornber,3 the agreement with experiment is really not impressive and the longitudinal part of the cross section is too large compared to the transverse part. Be-
The initial and final electrons with four-momenta \( k = (E; \vec{k}) \) and \( k' = (E'; \vec{k}') \) we take to be of zero mass. Then the invariant four-momentum transfer to the nucleon will be

\[
q^2 = (k - k')^2 = -4EE' \sin^2(\frac{1}{2} \theta),
\]

where \( \theta \) is the electron scattering angle. In the lab system, the energy of the virtual photon with momentum \( q = (\nu, \vec{Q}) \) will be

\[
\nu = E - E' = q \cdot p/m,
\]

assuming the target nucleon to be at rest with mass \( m \).

As shown by Bjorken and Walecka,\(^7\) the differential cross section for this process can be written

\[
\frac{d^2 \sigma}{d \Omega dE'} = \frac{\alpha^2}{4E^2 \sin^2(\frac{1}{2} \theta)} \times \left[ W_2(\nu, q^2) \cos^2(\frac{1}{2} \theta) + 2W_1(\nu, q^2) \sin^2(\frac{1}{2} \theta) \right]
\]

assuming unpolarized initial and final nucleon states. The two invariant structure functions \( W_1 \) and \( W_2 \) are defined in terms of electromagnetic current matrix elements:

\[
W_{\mu\nu} = 2m \left[ \left( \frac{P_\mu - q_\mu}{q^2} \right) \left( \frac{P_\nu - q_\nu}{q^2} \right) \frac{W_2}{m^2} \right. \\
+ \left. \left( \frac{g_{\mu\nu}}{q^2} - g_{\mu\nu} \right) W_1 \right]
\]

\[
= \sum_i (2\pi)^3 \delta^3(p + q - p') \langle p | J_{\mu}(0) | n \rangle \langle n | J_{\nu}(0) | p \rangle,
\]

where the sum extends over all final states \( | n \rangle \) with four-momentum \( p' \).

With only one nucleon resonance with mass \( M \) in the final state, \( W_{\mu\nu} \) takes the form

\[
W_{\mu\nu} = \langle p | J_{\mu}(0) | p' \rangle \langle p' | J_{\nu}(0) | p \rangle \delta(W^2 - M^2).
\]

Here \( W^2 = (p + q)^2 \) is the invariant mass squared of the produced \( N^* \).

The matrix elements

\[
\langle p | J_{\mu}(0) | p' \rangle = 2Mf_{\mu}
\]

must satisfy current conservation.
\begin{equation}
q_{\nu}(p|J_\mu(0)|p') = 0.
\end{equation}

Going to the rest system of the \(N^*\), where we take the space part of the photon four-momentum \(q_{\mu} = (\nu^*, Q^*)\) along the \(z\) axis, this requirement relates the scalar and longitudinal part of the current:

\begin{equation}
Q^* f_z = \nu f_z.
\end{equation}

In this frame, following Bjorken and Walecka, we can now express \(W_1\) and \(W_2\) in terms of \(f_z\) and \(f_{\perp}\), and \(f_{\perp}\) using Eq. (5):

\begin{align*}
W_1 &= \frac{1}{2} \left( |f_{\perp}|^2 + |f_z|^2 \right) \frac{M}{m} 5(W-M), \\
W_2 &= \frac{1}{2} \left( \frac{2|q^2|}{Q^*} \right) \frac{5}{M} |f_z|^2 - \frac{q^2}{Q^*} \left( |f_{\perp}|^2 + |f_z|^2 \right) \frac{m}{M} 5(W-M).
\end{align*}

(10)

Defining partial cross sections due to the transverse and longitudinal parts of the photon by

\begin{align*}
\sigma_{\perp}(W) &= \frac{4\pi\alpha}{K^*} \frac{1}{2} \left( |f_{\perp}|^2 + |f_z|^2 \right) \frac{\Gamma}{2\pi} \delta (W-M), \\
\sigma_{\parallel}(W) &= \frac{4\pi\alpha}{Q^*} \left( \frac{q^2}{Q^*} \right) |f_z|^2 \frac{\Gamma}{2\pi} \delta (W-M),
\end{align*}

(11)

we can now write the differential cross section, Eq. (4), as

\begin{equation}
\frac{d\sigma}{d\Omega} = \frac{\alpha}{4\pi^2} \frac{\cos^2(\frac{1}{2}\theta)}{4E\sin(\frac{1}{2}\theta)} \times \left( \frac{-q^2}{Q^*} \right) \frac{1}{\varepsilon} (\sigma_{\perp} - \epsilon \sigma_{\parallel}),
\end{equation}

(12)

where

\begin{equation}
\varepsilon^{-1} = 1 + 2 \left( \frac{1}{1 - \frac{\nu^2}{Q^2}} \right) \tan^2(\frac{1}{2}\theta).
\end{equation}

(13)

Instead of the cross sections \(\sigma_1\) and \(\sigma_2\), experimental data are usually given for the slightly different quantities \(\sigma_{\perp}\) and \(\sigma_{\parallel}\) introduced by Hand:

\begin{align*}
\sigma_{\perp} &= \frac{Q}{K} \sigma_{\parallel}, \\
\sigma_{\parallel} &= \frac{Q}{K} \sigma_{\perp}.
\end{align*}

(14)

Here \(K\) is the lab energy required to produce the \(N^*\) with real photons

\begin{equation}
K = (M^2 - m^2)/2m.
\end{equation}

(15)

Inserting \(\sigma_{\perp}\) and \(\sigma_{\parallel}\) into Eq. (12), we get the well-known expression

\begin{equation}
\frac{d\sigma}{d\Omega} = \Gamma_{\perp} \sigma_{\perp} + \Gamma_{\parallel} \sigma_{\parallel} = \Gamma_{\perp} (\sigma_{\perp} - \epsilon \sigma_{\parallel}),
\end{equation}

(16)

with

\begin{equation}
\Gamma_{\perp} = \frac{\alpha}{4\pi^2} \left( \frac{-K}{q^2} \right) \frac{E'}{E} \frac{2}{1 - \epsilon}.
\end{equation}

(17)

The polarization parameter \(\epsilon\) varies between 0 and 1.

From Eq. (11) we get for \(\sigma_{\perp}\) and \(\sigma_{\parallel}\):

\begin{align*}
\sigma_{\perp}(W) &= \frac{4\pi\alpha}{K^*} \frac{1}{2} \left( |f_{\perp}|^2 + |f_z|^2 \right) \frac{\Gamma}{2\pi} \delta (W-M)^2 + \Gamma^2/4, \\
\sigma_{\parallel}(W) &= \frac{4\pi\alpha}{Q^*} \frac{q^2}{Q^*} |f_z|^2 \frac{\Gamma}{2\pi} \delta (W-M)^2 + \Gamma^2/4,
\end{align*}

(18)

where we have made the substitution

\begin{equation}
\delta (W-M) = -\frac{1}{\pi} \frac{\Gamma/2}{(W-M)^2 + \Gamma^2/4}
\end{equation}

(19)

valid for an unstable resonance having a total width \(\Gamma\). \(K^*\) is the quantity \(K\) evaluated in the \(N^*\) rest frame

\begin{equation}
K^* = (M^2 - m^2)/2m,
\end{equation}

(20)

\begin{equation}
f_{\perp} = f_z,
\end{equation}

(21)

so that \(f_{\perp}\) and \(f_z\) correspond to photons with positive and negative helicity in the rest frame of \(N^*\) where the initial nucleon has \(J_z = \frac{1}{2}\).

In Sec. III we will calculate the matrix elements \(f_{\perp}\), \(f_z\), and \(f_{\parallel}\) for the all the relevant nucleon resonances in the symmetric quark model. Equation (18) can then be used to get the peak cross sections \(\sigma_{\perp}(M)\) and \(\sigma_{\parallel}(M)\) which can be directly compared with experiment.

### III. CURRENT MATRIX ELEMENTS

The relativistic symmetric quark model we will use here, as developed in Ref. 4, pictures the baryon as three quarks held together by pairwise harmonic forces. This system is described by the operator

\begin{equation}
K = 3(p_x^2 + p_y^2 + p_z^2) + \frac{1}{36} \Omega^2 \left[ (u_x - u_y)^2 + (u_y - u_z)^2 + (u_z - u_x)^2 \right] + C,
\end{equation}

(22)

where \(p_x\) is the four-momentum of quark \(a\) with coordinate \(u_x\). \(C\) is some unknown constant to describe the departure from this simple model. Introducing the total momentum \(P\) of the system and two internal momenta \(\xi\) and \(\eta\),

\begin{align*}
p_x = \frac{1}{3} P - \frac{1}{3} \xi, \\
p_y = \frac{1}{3} P + \frac{1}{3} \xi - \frac{1}{2\sqrt{3}} \eta, \\
p_z = \frac{1}{3} P + \frac{1}{3} \xi + \frac{1}{2\sqrt{3}} \eta,
\end{align*}

(23)

then Eq. (22) can be written

\begin{equation}
K = P^2 - \mathcal{M}^2,
\end{equation}

where

\begin{equation}
-\mathcal{M}^2 = \frac{1}{4} (\xi^2 + \eta^2) + \frac{1}{4} \Omega^2 (x^2 + y^2) + C.
\end{equation}

(24)
Here \(x\) and \(y\) are coordinates conjugate to \(\xi\) and \(\eta\). To discuss the mass spectrum following from this internal motion, it is more convenient to use the creation operators
\[
a^\dagger = \left( \frac{1}{\Omega} \right)^{1/2} \xi^* + i \left( \frac{\Omega}{2} \right)^{1/2} x^* ,
\]
\[
b^\dagger = \left( \frac{1}{\Omega} \right)^{1/2} \eta^* + i \left( \frac{\Omega}{2} \right)^{1/2} y^* ,
\] (25)
and their Hermitian conjugates \(a\) and \(b\). In terms of these, Eq. (24) takes the form
\[
-\mathcal{M}^2 = \Omega (a^\dagger a + b^\dagger b) + C .
\] (26)

The eigenvalues of this operator give an equally spaced spectrum in mass squared, each excitation corresponding to \(\Omega = 1.05 \text{ GeV}^2\).

In the symmetric quark model, every physical baryon state is required to be totally symmetric under any interchange of its quark labels. Consequently, each excited state must be combined with the appropriate SU(6) state to give over-all symmetry under combined interchange of both SU(6) and spatial quark labels. The lowest SU(6) \(\otimes\) O(3) multiplets resulting from this restriction are listed in Table I together with their decomposition into \(2s^1(SU(3))\) multiplets, \(S\) being the quark spin of the SU(3) multiplet and \(J\) the total angular momentum. Each multiplet is identified by one representative particle: the \(N\) in octets, the \(\Delta\) in decimets, and the \(\Lambda\) in singlets. The multiplets with a question mark in front are not yet established, but they are predicted to exist. Their mass follows from the extra assumption of negligible spin-orbit forces.

The electromagnetic interaction of the baryons is obtained in this model through the minimal coupling
\[
p_{\mu} = p_{\mu} - e A_{\mu} ,
\] (27)
for each quark four-momentum \(p_{\mu}\). As shown in Ref. 4, this gives for the coupling to a photon with polarization \(e_{\mu}\) in the rest system of the \(N^*:\)

\[
Q^{*2} = \frac{(M^2 - m^2 + q^2)^2}{2M^2} .
\] (30)

we get from Eq. (28) for the current matrix elements
\[
f_0 = 9G \langle N^* | a_s, (2) S | N^*(+) \rangle ,
\]
\[
f_\pm = 9G \langle N^* | a_s, (T \pm Ra_{\pm}) | N^*(\pm) \rangle ,
\]
\[
f_\mp = 9G \langle N^* | a_s, (T \mp Ra_{\mp}) | N^*(-) \rangle ,
\] (31)
where
\[
\lambda = \left( \frac{2}{\Omega} \right)^{1/2} Q^*, \quad T = \frac{1}{3M} \left( \frac{\Omega}{2} \right)^{1/2} ,
\]
\[
S = + \left( 3Mm + q^2 - m^2 \right)/4M^2 ,
\]
\[
R = \sqrt{2} \left( \frac{Q^*}{M + m} \right)^{1/2} ,
\] (32)
and
\[
(Q^*/\nu^*) f_x = cS - c(M^2 - m^2 - N\Omega)/6M^2 .
\] (33)

From Eq. (28) we find
\[
f_\pm = cS ,
\]
\[
(Q^*/\nu^*) f_x = cS\cdot c(M^2 - m^2 - N\Omega)/6M^2 .
\] (34)

where \(c\) is some numerical constant and \(N\) is the number of excitations in the \(N^*\).

In this model, all particles are on straight exchange-degenerate trajectories with masses\(M^2 = m^2 + N\Omega\), \(m\) being the mass of the ground state. The last term in Eq. (34) will then be zero and the current conservation condition, Eq. (9), is satisfied.

To be consistent at this point, we should also use the model values of the particle masses in the numerical calculations of the scattering amplitudes. This would, however, bring us into trouble with the kinematical factors entering the cross-section formulas where we must use the physical masses of the particles involved. Consequently, we will in the following use the real particle masses in all expressions. In the cases considered, this makes little difference in the numerical

results of the model.

In particular, for the $F_{15}(1688)$ which is the Regge recurrence of the nucleon, one should expect the calculated amplitudes to be in the best agreement with experiment. As discussed in Sec. I, this is apparently not the case.

Using the Appendix in Ref. 4, it is a simple matter to evaluate the matrix elements in Eq. (31). The results are given in Table II where we have only included those resonances with mass $M < 1750$ MeV, this being the region of interest here.

IV. RESULTS AND DISCUSSION

The form factor $G$ does not follow from this model as discussed in Ref. 4. Our lack of theoretical understanding at this point forces us to guess its form and see how that guess compares with experiment. We have one serious restriction on our choice. It should, in the simple case of elastic electron scattering, give the proton dipole form factor. With this in mind, we will in the following use one of the simplest possible forms:

$$G(M, q^2) = \left(1 - \frac{q^2}{0.71}\right)^2 \left(1 - \frac{q^2}{4M^2}\right)^{(1-n)/2}, \quad (35)$$

where $N$ is the number of excitations in the $N^*$. This arbitrary choice seems to give a reasonable description of the present experimental data in the limited resonance region we are concerned with here. From Eq. (50) in Ref. 4, we get for the proton magnetic form factor with this assumed form, Eq. (35):

$$\frac{G_M}{\mu} = \left(1 - \frac{q^2}{0.71}\right)^2 . \quad (36)$$

We are now in the position to calculate the cross sections $\sigma_T$ and $\sigma_S$, Eq. (18), for each state in Table II. The results of the numerical work are presented in Figs. 3, 4, and 5 where we plot each cross section for proton target at the resonance peak $W = M$ as a function of $-q^2$.

The scalar cross section for the $P_{33}(1236)$ is zero since this resonance has quark spin $S = \frac{3}{2}$. Both $\sigma_T$ and $\sigma_S$ vanish for all the three states $S_{11}(1700)$, $D_{13}(1700)$, and $D_{15}(1670)$ of the quark spin $S = \frac{3}{2}$ octets of the $[70, 1^-]$. The reason is that the electromagnetic coupling between two octet protons being proportional to $F + \frac{1}{2}D$ vanishes for these states since they all have $I^G = -\frac{1}{2}$.

In Fig. 5 we have also included cross sections for the $P_{33}(1690)$, existing in the footnotes of the Particle Tables,10 and the not-yet-established $P_{33}(1700)$ with an assumed width of $\Gamma = 200$ MeV just to find out how important the contributions from these resonances are.

From Fig. 1 we see that there are three prominent bumps in the inelastic electron-proton cross section. The dominant peak is at $W = 1236$ MeV, corresponding to the $P_{33}(1236)$ resonance. The next bump is at $W = 1525$ MeV and the last at $W = 1680$ MeV. There is also some structure...
around $W = 1920$ MeV which we will not discuss here because of its dubious resonance nature.\cite{11,12}

The second and third peaks can be qualitatively understood in terms of the resonances listed in Table II. Besides the $P_{33}(1236)$ and the Roper resonance $P_{11}(1470)$ which has a small cross section, the resonances are grouped into two distinct mass regions. The first group consists of the $S_{11}(1535)$ and the $D_{13}(1520)$ corresponding to the second bump. The remaining resonances, grouped around $W = 1680$ MeV, are the $S_{11}(1560)$, $D_{13}(1670)$, $D_{33}(1670)$, $F_{15}(1688)$, $P_{33}(1690)$, $S_{11}(1700)$, $D_{13}(1700)$, and $P_{13}(1700)$.

To make a quantitative comparison with experiment, we have in Fig. 3 for the $P_{33}(1236)$ plotted the experimental values of $\Sigma = \sigma_T + \epsilon_5 \sigma_S$ as evaluated by Clegg.\cite{12} For $-q^2 < 0.5$ GeV$^2$, we see that the theoretical cross section is almost 30% too small. For larger $-q^2$, the agreement is very good. The values of $\Sigma$ at the second resonance peak we compare with the sum of the cross sections of $S_{11}(1535)$ and $D_{13}(1520)$ in Fig. 6. Again we find very good agreement. At small $-q^2$, the largest contribution is coming from the $S_{11}(1535)$, contrary to what is usually assumed in the literature.\cite{11,12}

Doing the same for the third peak, Fig. 7, we note that good agreement is obtained only when including the predicted resonance $P_{13}(1700)$. Without its contribution we would get a cross section around 30% too small as compared with the experimental data of Clegg.\cite{12}

It is generally believed that this third bump in the cross section is mainly $F_{15}(1688)$.\cite{11,12} According to the present model, that is not the case, the $D_{33}(1670)$ being just as important. Had we tried to use the $F_{15}(1688)$ alone, we would be off by a factor of 3 in the cross section. This may explain the apparent disagreement for this resonance in the photoproduction amplitude which experimentally is found by fits not including all the important resonances in the same mass region like the $D_{33}(1670)$.\cite{13}

In other words, had the $F_{15}(1688)$ alone been able to explain the third peak, then this model would be in serious trouble. The same would obviously have been the case if we had gotten good agreement not taking into account the not-yet-observed $P_{13}(1700)$.

Another interesting result of this model is the small scalar cross section $\sigma_S$ we find. The maximum of the ratio $\sigma_S/\sigma_T$ reached at $-q^2 = 0.5$ GeV$^2$
so $\sigma_5$ will also have a zero in the resonance region in the range $-q^2 = 3 - 4 \text{ GeV}^2$. This result is obviously independent of the arbitrary form factor we have used.

A completely different approach to the process of electroproduction of nucleon resonances has been taken by Pritchett, Walecka, and Zucker\textsuperscript{15} and Pritchett and Zucker.\textsuperscript{16} They have used a coupled-channel relativistic N/D model to calculate the excitation amplitudes for most of the resonances considered in this paper. The magnitudes of the first three resonance peaks in the cross section obtained in this model agree fairly well with experiment. However, it also predicts that the scalar cross section should dominate at the second peak beyond $-q^2 = 4 \text{ GeV}^2$ and at the third peak when $-q^2 > 1 \text{ GeV}^2$. The new measurements of $\sigma_5$ in this resonance region\textsuperscript{14} seem to be in disagreement with these predictions.

V. CONCLUSION

The resonance region of inelastic electron-proton scattering has been investigated in a relativistic quark model. We have found good agreement with all aspects of the present experimental situation. The second peak in the inelastic cross section is well described by the resonances $S_{11}(1535)$ and $D_{15}(1520)$. To obtain good agreement for the third peak, we need to include, besides the $F_{15}(1688)$, the $D_{13}(1670)$ and a not-yet-observed resonance $P_{13}(1700)$ whose existence is predicted from this symmetric quark model. We find a small cross section for the Roper resonance $P_{11}(1470)$ which is also in accordance with experiment. The scalar cross section $\sigma_s$ is smaller than $\sigma_T$ in the whole resonance region considered.

We look forward to more precise experiments for small $-q^2$ which would test our choice of form factor. Future coincidence experiments will be important to check the composition of each bump of the inelastic cross section.

\textsuperscript{4}R. P. Feynman, M. Kieflinger, and F. Ravndal, Phys. Rev. D 3, 2706 (1971). The metric used is such that for a four-momentum $p' = (E', \vec{p})$, $p^2 = p_\mu p^\mu = E^2 - \vec{p}^2 = m^2$. The states $|\rho\rangle$ have the invariant normalization $\langle \rho' | \rho \rangle = (2\pi)^4 2 E \delta^4(\vec{p} - \vec{\rho})$ and $\bar{u}u = 2m$.

Two-Body Weak Reactions of Hadrons at Very High Energies*

Department of Physics and Lawrence Radiation Laboratory, University of California, Berkeley, California 94720

(Received 2 April 1971)

Two-body hadronic scattering through weak interactions is investigated theoretically in the energy region accessible at the National Accelerator Laboratory. In the ordinary current-exchange form of weak interactions, the following quantities are calculated for charge-exchange weak hadronic reactions: (i) the differential cross section, the polarization of a final baryon, and the asymmetry in the angular distribution of scattering from a polarized target for strangeness-changing processes, and (ii) the interference of weak-interaction amplitudes with strong-interaction amplitudes for processes to which both weak and strong interactions contribute. The interference with strong amplitudes is discussed by means of a straight extrapolation of existing Regge analysis at lower energies (less than 30 GeV). Differential cross sections near the forward direction are typically of the order of $10^{-38}$ cm$^2$ in $d\sigma/d\cos\theta$ in the center-of-mass frame. The interference between weak and strong amplitudes is unfortunately only one part in $10^8$ for the $\pi\pi$ charge-exchange scattering in spite of the different high-energy behavior. All calculations are supposed to be valid at high energies up to absorption corrections due to a Regge cut generated by the Pomeronchukon and a fixed pole at $J=1$ from the weak amplitude. Inelastic scattering is also briefly mentioned. Charge-exchange processes are discussed in connection with a test for the existence of neutral weak currents.

I. INTRODUCTION

The structure of weak interactions is fairly well known in the low-momentum-transfer region through semileptonic and purely leptonic decay processes. In contrast, purely hadronic weak interactions are less understood, partly because of complications caused by strong interactions. For instance, neutral weak currents have frequently been discussed in connection with the $\Delta I = \frac{1}{2}$ rule, $CP$ violation, and so forth; while their absence is now established to a very good accuracy in semileptonic and leptonic interactions, little can be said about purely hadronic processes.

A cutoff momentum characteristic of weak interactions has been extensively discussed from various viewpoints, recently by means of current algebras. Some current-algebra calculations indicate a surprisingly low value of the cutoff momentum as compared with a unitarity cutoff (~300 GeV), although they are partly based on a somewhat controversial technique. It is very interesting to see how our weak-interaction theory, which has successfully described low-energy decay phenomena aside from $CP$-violating phenomena, must be modified at a short distance. Reactions induced by neutrinos have been thoroughly discussed, since one can develop fairly straightforward arguments similar to those used for electroproduction as measured at SLAC. However, purely hadronic interactions have seldom been considered seriously. The purpose of this paper is to report results of our calculation of various quantities which may possibly be measured in future experiments on purely hadronic weak interactions at high energies.

We shall first consider two-body reactions. The current-exchange theory of weak interactions gives rise to a fixed pole at $J=1$ in the $t$-channel complex angular momentum plane. The fixed pole appears in the $t$ channels for reactions with $I=1$, $S=0$, and $|Q|=1$ and with $I=\frac{1}{2}$, $|S|=1$, and $|Q|=1$. We shall not take into account higher orders of
